Feeding practices and reducing cross suckling

Some producers have expressed concerns about undesirable behaviors when calves are housed in social groups. This includes worries about the opportunity for calves to cross suck on each other. Others wonder about how to minimize milk stealing. In this article, we discuss calves’ natural feeding behavior. An understanding of calf behavior informs research-based solutions to reduce cross suckling, pen-directed sucking, and milk stealing.

Understanding Feeding Behavior

To understand why dairy calves sometimes show undesirable or abnormal behaviors, we can look to their natural behaviors. Older studies in extensive (pasture-based) dairy systems found when calves were reared with their dams, they suckled 4 to 10 times daily for 7 to 10 minutes at a time. These calves were rarely observed cross sucking on other calves. In grazing systems, calves learn about feeding while living in social groups. They begin to sample forages from a young age. The natural weaning process would occur when calves are around 10 months old. In beef cow-calf systems, calves are typically weaned at around 6 months of age. Dairy calves are typically weaned at a few weeks of age.

When raised without their dams, dairy calves show suckling behavior at any time of day. However, most suckling occurs around the time of each milk meal. When calves begin a meal of milk or milk replacer and taste lactose, their instinctive suckling behavior is stimulated. The desire to suckle is likely to continue for at least 20 minutes, even after the calves have finished drinking. This post-meal suckling may be directed toward objects in the pen or hutch, such as the fencing or buckets. Suckling can also be directed toward the body parts of other calves (i.e., cross sucking). Post-meal suckling does serve a function of promoting digestion and fullness in calves by stimulating the release of digestive hormones.

How Much of a Problem is Cross Sucking?

In a survey conducted at the end of 2019, we asked producers to estimate how often they observed their pre-weaned calves cross suck: never, occasionally, sometimes, or frequently. On 318 farms using individual housing for their pre-weaned calves, 29% reported their calves had tactile contact, for example through the mesh panels of adjacent pens. Within these farms providing tactile contact, 70% observed at least occasional cross sucking while the calves were housed individually, with 7% describing this behavior as frequent. Among the 95 farms using pair or group housing, 85% reported at least occasional cross sucking, with 11% describing it as frequent. These data show occasional cross sucking is seen on most farms with pair- or group-housed calves as well as on farms housing calves individually with mesh pen-dividers. However, only a small percentage of producers observe frequent cross suck in either housing type.

Excessive cross sucking is thought to lead to frostbitten ears, navel infections, mastitis, or udder damage. Producers perceive the behavior as a nuisance and have expressed worries about the potential for blind quarters. However, the few studies evaluating the potential negative outcomes of cross sucking have not found consistent relationships.

For example, across 25 farms in Austria, researchers did not find an association between the incidence of navel infections and the amount of cross sucking shown by pre-weaned calves. Another long-term study in Canada found a small number of calves continued to cross suck when moved to large groups after weaning. Offending calves targeted specific pen-mates but did not indiscriminately cross suck on all other calves in the pen. When heifers experiencing persistent cross sucking reached their first lactation, they did not have higher somatic cell counts or greater incidence of mastitis.

Nose Flaps

Producers commonly try to stop calves from cross sucking by applying plastic nose flaps to the septum. When calves with nose flaps try to cross suck, other calves react to the feeling of the hard, protruding flap and push away the offender. Unfortunately, nose flaps do not address the underlying motivation to suck. When the nose flap is removed, the offender may start cross sucking again.

There is no silver bullet for eliminating cross sucking because young calves are strongly motivated to suckle. However, several feeding strategies have been shown by many studies to reduce or redirect the behavior more appropriately.

**Milk or Milk Replacer Allowance**

Many experts now recommend feeding calves at least 8 to 10 quarts per day of milk or milk replacer. This recommendation is regardless of whether calves are housed individually or in pairs or groups and regardless of the season or climate.

Some in the industry still advocate for the traditional practice of feeding calves only 10% of their bodyweight, or approximately 4 to 6 quarts per day. This was intended to encourage solid feed intake and rumen development. However, restricted milk feeding is now considered outdated. Although calves start sampling solids early in life, they still need to rely on nutrients from milk for growth before 3 weeks of age. Calves on restricted milk programs show signs of chronic hunger in several studies.

When offered the chance to drink as much milk or replacer as they choose, calves consume about 20% of their bodyweight per day. Some producers feed calves an enhanced milk allowance by 3 weeks of age, ramping up from smaller amounts starting in the first week of life. A study found when calves were fed the peak milk allowance from day 1 of life, they grew better – and with no detrimental effects on health – compared to when milk allowances were ramped up during the first 1 to 2 weeks of life. In fact, calves are capable of drinking 10 quarts per day even in the first week of life. When fed only 4 quarts per day, calves lose weight in the first week of life.

Calves drinking more milk or replacer defecate more because of increased hydration. Feeding a high plane of nutrition using whole milk or modern, high quality milk replacer is not associated with abnormal manure. Research has not detected negative impacts of enhanced milk feeding on gut health, insulin sensitivity, or abomasal overflow into the rumen. In fact, calves on an enhanced milk replacer allowance recovered faster from diarrhea after an experimental *cryptosporidium* challenge. They also showed better average daily gain and feed efficiency.

In a 2019 survey, we found encouraging data on current feeding practices on U.S. farms (*Figure 1*). Most farms fed their 4-week-old calves 8 quarts per day or more of milk or milk replacer. Among farms using individual housing, 50% fed at least this amount. Among farms housing their calves in pairs or groups, 66% fed at least 8 quarts per day. Twenty-nine percent of farms with individual housing fed 10 quarts or more per day, compared to 12% of farms with individual housing.

When housing calves in pairs or groups, feeding a high plane of milk nutrition is a key practice to provide a strong foundation for good health and welfare outcomes. Cross sucking is partially influenced by hunger and increases when calves are on restricted milk or milk replacer programs. Increasing the daily milk allowance is one way to reduce cross sucking.

Meal length also matters because calves prefer to suckle for a certain length of time. If calves spend insufficient time suckling while drinking, they will continue to be motivated to suckle on other objects in their surroundings. To increase meal length, nipples designed to deliver a slower flow rate are recommended. Neonatal calves may initially need a softer “colostrum” nipple before they transition to harder slow-flow nipples.

In automatic milk feeding (“autofeeder”) systems, calves sometimes cross suck even when daily allowances are set to *ad libitum*. Although there is not yet research on this topic, we suspect this could occur if the meal size settings are too small. With small, short meals, calves may not only remain hungry, but could also still be motivated to suckle after they finish drinking. Cross sucking could also occur with too many calves in a group because only one calf can access the nipple at a time. Calves may not be able to drink as much as they want due to competition. They may also be motivated to suckle when the feeder is unavailable. It is important to make sure all calves have sufficient access to the feeder and to adjust meal size limits to mimic natural feeding patterns (see *Understanding Feeding Behavior* on the previous page). For more on group size, see the *Grouping Strategies* article in this series.
Providing Nipples to Reduce Cross Sucking

In the U.S., producers commonly start neonatal calves on bottles then transition them to buckets. In our 2019 survey, 71% of producers using individual housing fed milk or replacer in buckets. In contrast, only 20% of producers housing calves in pairs or groups fed in buckets or open troughs. Instead, 80% of those farms fed pair- or group-housed calves with bottles, teat buckets, or autofeeder systems with a nipple. This is good news because many studies have shown nipple feeding significantly reduces cross sucking compared to bucket feeding.

Feeding through a nipple gives calves an appropriate outlet for their suckling instinct, both while drinking and afterward. Nipples designed to deliver slow flow rates are effective for extending the meal length. It is important to allow calves access to a nipple for at least 20 minutes after they finish the milk meal. Because bottles need to be removed after each meal for cleaning, it is important for management protocols to allow calves enough time to finish sucking.

When providing prolonged access to a milk nipple is not feasible, an alternative is to provide standalone nipples to serve as pacifiers. These can remain in the pen. When calves are fed milk through teats or given pacifiers, they show the same drinking postures and head-butting behaviors as they would when nursing from their dam. This shows having access to an artificial nipple provides an appropriate outlet for their natural behavior.

Recently at UW-Madison, we tested several feeding strategies for pair-housed calves. Calves were bottle fed until they were 2 weeks old, when they were switched to either standard buckets or slow-flow Milk Bar® teat buckets (Photo 1). All calves were fed 8 quarts of pasteurized milk across 2 daily meals. Half of the calves were fed starter grain in a bucket. The other half had both a bucket and a Braden Start® bottle (Photo 2), which has a specialized nipple allowing solids to pass through.

Calves fed milk using the slow-flow teats spent more time drinking milk and less time sucking on their water buckets, hutches, fencing, and – most importantly – each other. Calves fed milk from open buckets had significantly less cross sucking when they also had a Braden Start® bottle. The Braden Start® bottle stayed on the fencing and required less management than the teat buckets. Still, feeding milk with slow-flow teats was the most effective strategy for reducing all abnormal suckling behaviors.

Reducing Milk Stealing

Some producers claim healthy competition motivates pair- or group-housed calves to eat better. Research suggests social housing has positive influences on feeding behavior and growth. Calves prefer to eat at the same time as their companions. At maturity, previously group-housed calves gain better access to resources. However, too much competition, when calves have unequal access to feeding space, can mean some calves fall behind.

Producers can use several strategies to reduce milk stealing. Individual milk containers can be mounted at opposite ends of the pen to create distance between the calves while drinking. If using mob feeders, consider providing more teats than calves in a group. For example, for a group of 3 of calves, use a teat bucket with at least 4 milk compartments and teats. Research has shown barriers between calves (at least 1 meter or 3’ 3” long) can reduce milk stealing. Some farms even create makeshift “feeding stalls” using wire fencing panels as barriers. Other farms install mini-headlocks in group pens.

In our 2 studies at UW-Madison, calves paired in connected hutches showed very little milk competition. In one study, calves had slow-flow Milk Bar® nipples attached to 4-quart bottles. In the other study, calves had slow-flow
Milk Bar® teat buckets (Photo 1). With the teat buckets, calves sometimes pushed each other off the nipple after the milk was gone. This was likely because they could not see into the opaque plastic buckets. Although the calves looked like they were competing, they were not stealing milk from each other.

Note the size or age difference between calves in a pair or group may affect competition. See the Grouping Strategies article in this series for more information.

Providing Hay

Feeding hay to pre-weaned calves is relatively uncommon in the U.S., although it is mandated in parts of Europe. When given the opportunity, calves consistently choose to eat a fraction of hay in their diet. A study found dairy calves sorted mixed rations of texturized starter and chopped hay to eat the hay, even when only a few weeks old. Compared to starter alone, eating both hay and starter increases rumen size and rumen pH (i.e., reduces the acidity). Eating forages is part of the natural behavior of cattle. When hay is not provided, young calves will eat straw bedding. Feeding chopped hay can provide an appropriate behavioral outlet. This practice has been found to reduce abnormal pen-directed suckling.

Weaning Strategies

Weaning is a stressful period for all calves. Regardless of how they are housed before weaning, cross sucking can appear or increase when calves move to group housing after weaning. Because cross sucking is related to hunger, calves better established on solid feed are less likely to cross suck. Instead of abrupt weaning by taking milk away cold turkey, use a gradual or step-down weaning strategy. This is important to ease the transition during this stressful period and to reduce cross sucking.

In our 2019 survey, among the 95 farms housing their calves in pairs or groups, only 4% used abrupt weaning. Similarly, among the 318 farms with individual housing, only 7% used abrupt weaning. The rest of the farms stepped down the milk allowance by reducing the size of each milk meal, reducing the number of meals per day, or a combination.

Calves should begin the weaning process no earlier than 6 weeks of age. Calves fed a greater allowance of milk or replacer will initially consume less grain. To properly develop the rumen, calves should be eating at least ½ lb of grain for 21 to 28 days. Weaning needs to be carefully managed to encourage proper intakes and weight gain. Calves on a higher plane of milk nutrition will likely wean at a later age than calves on a restricted milk program.

Remember, social housing and enhanced milk feeding go hand in hand. A study found when pair-housed calves were fed a milk allowance of 9.5 quarts per day, they ate more grain during weaning compared with calves fed only 5.3 quarts per day. For calves fed the recommended 8 quarts per day or more, milk should be reduced across a period of about 10 days. Sufficient time is needed for calves to increase their grain intake and for the gut adjust to a solid-feed diet. Milk feeding should not completely stop until calves reach 8 weeks of age or older.

According to the Dairy Calf and Heifer Association (DCHA) Gold Standards, calves with a target weaning age of 8 weeks of age or older should ideally be eating 4 to 5 lbs per day of grain for 3 days in a row.

Most farms in our 2019 survey followed the 8-weeks-of-age guideline. Regardless of peak milk allowance, 75% of the farms with individual housing and 71% of the farms using pair or group housing completely weaned their calves at 8 weeks of age or older.
